

***Analysis of
EEG/MEG Map Topographies and
Source Distributions
on the Epoch Level using
Non-parametric Randomization Tests***

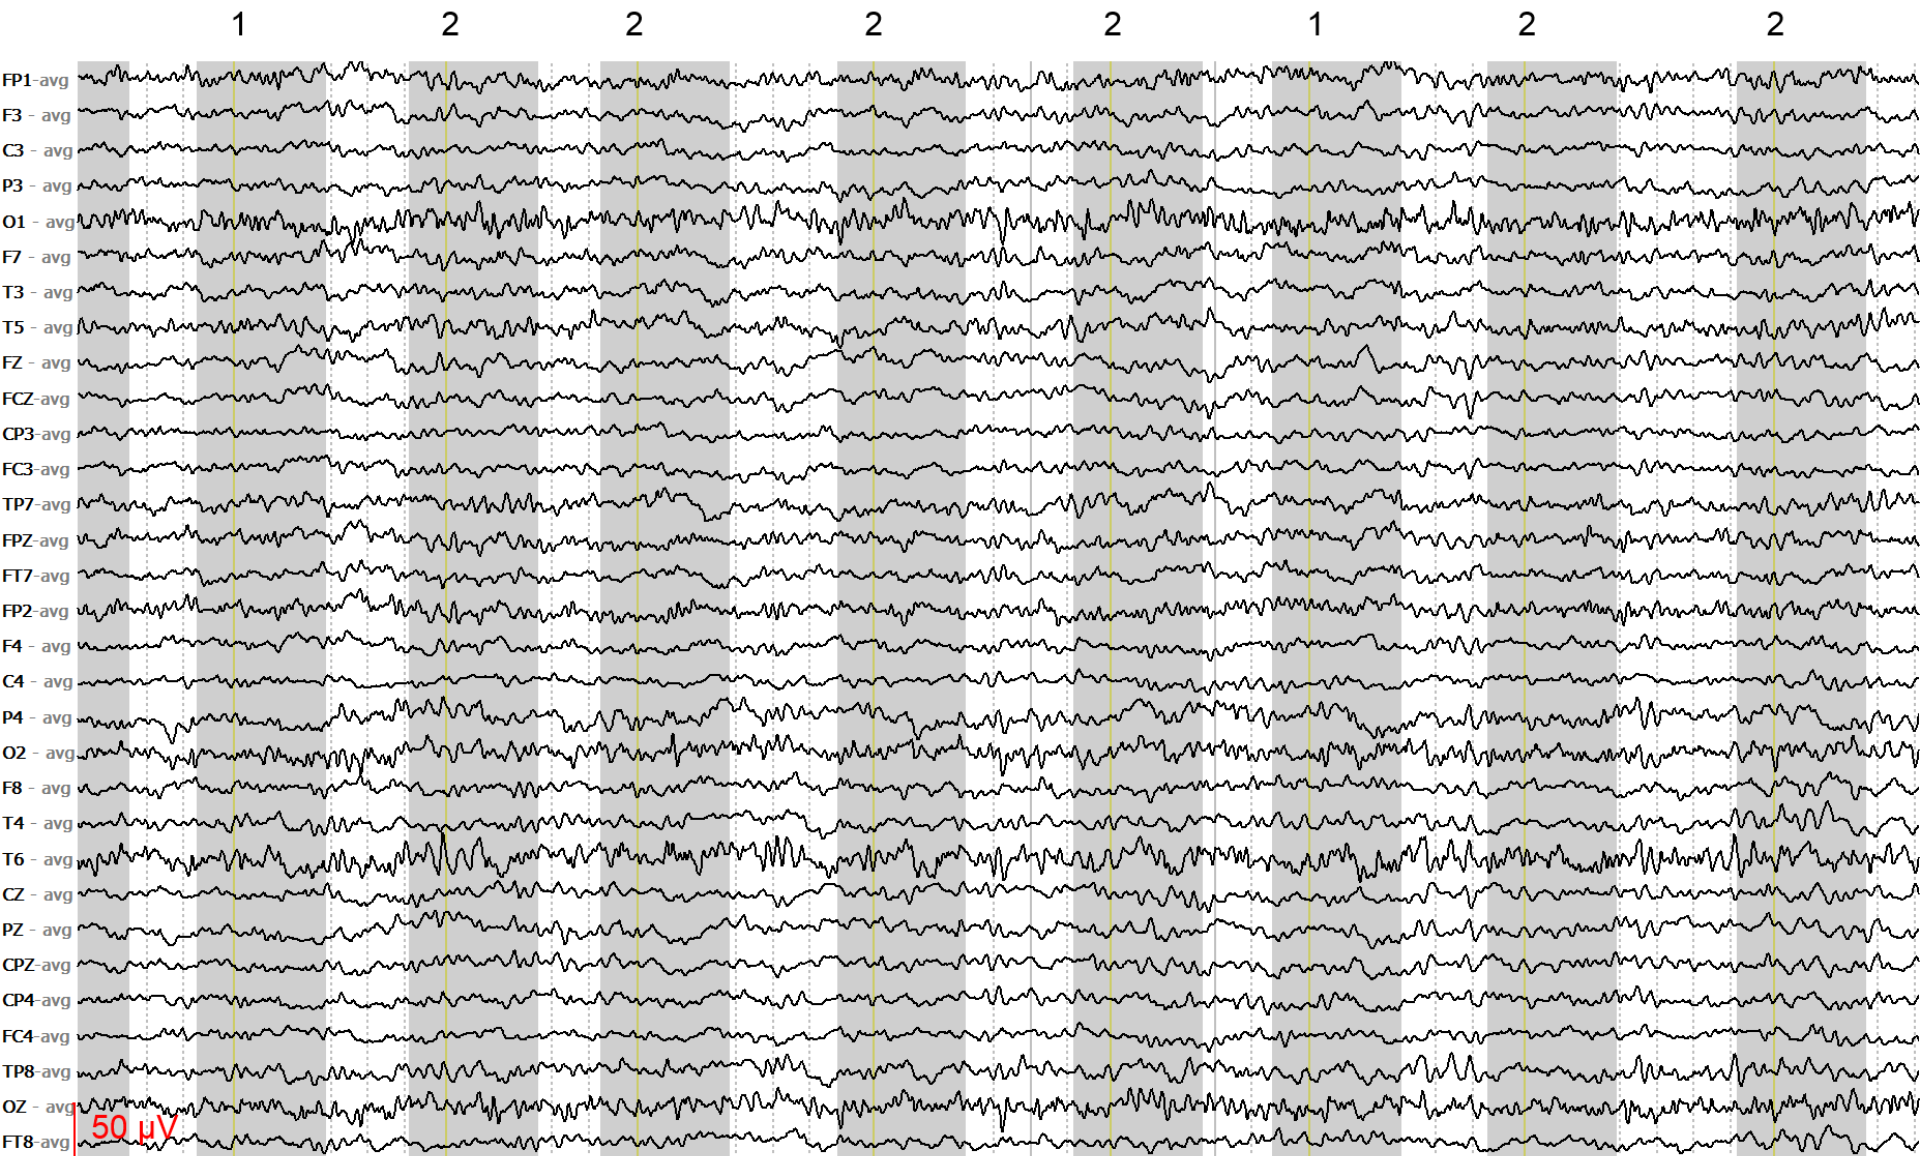

Michael Wagner

Compumedics Neuroscan, Hamburg, Germany

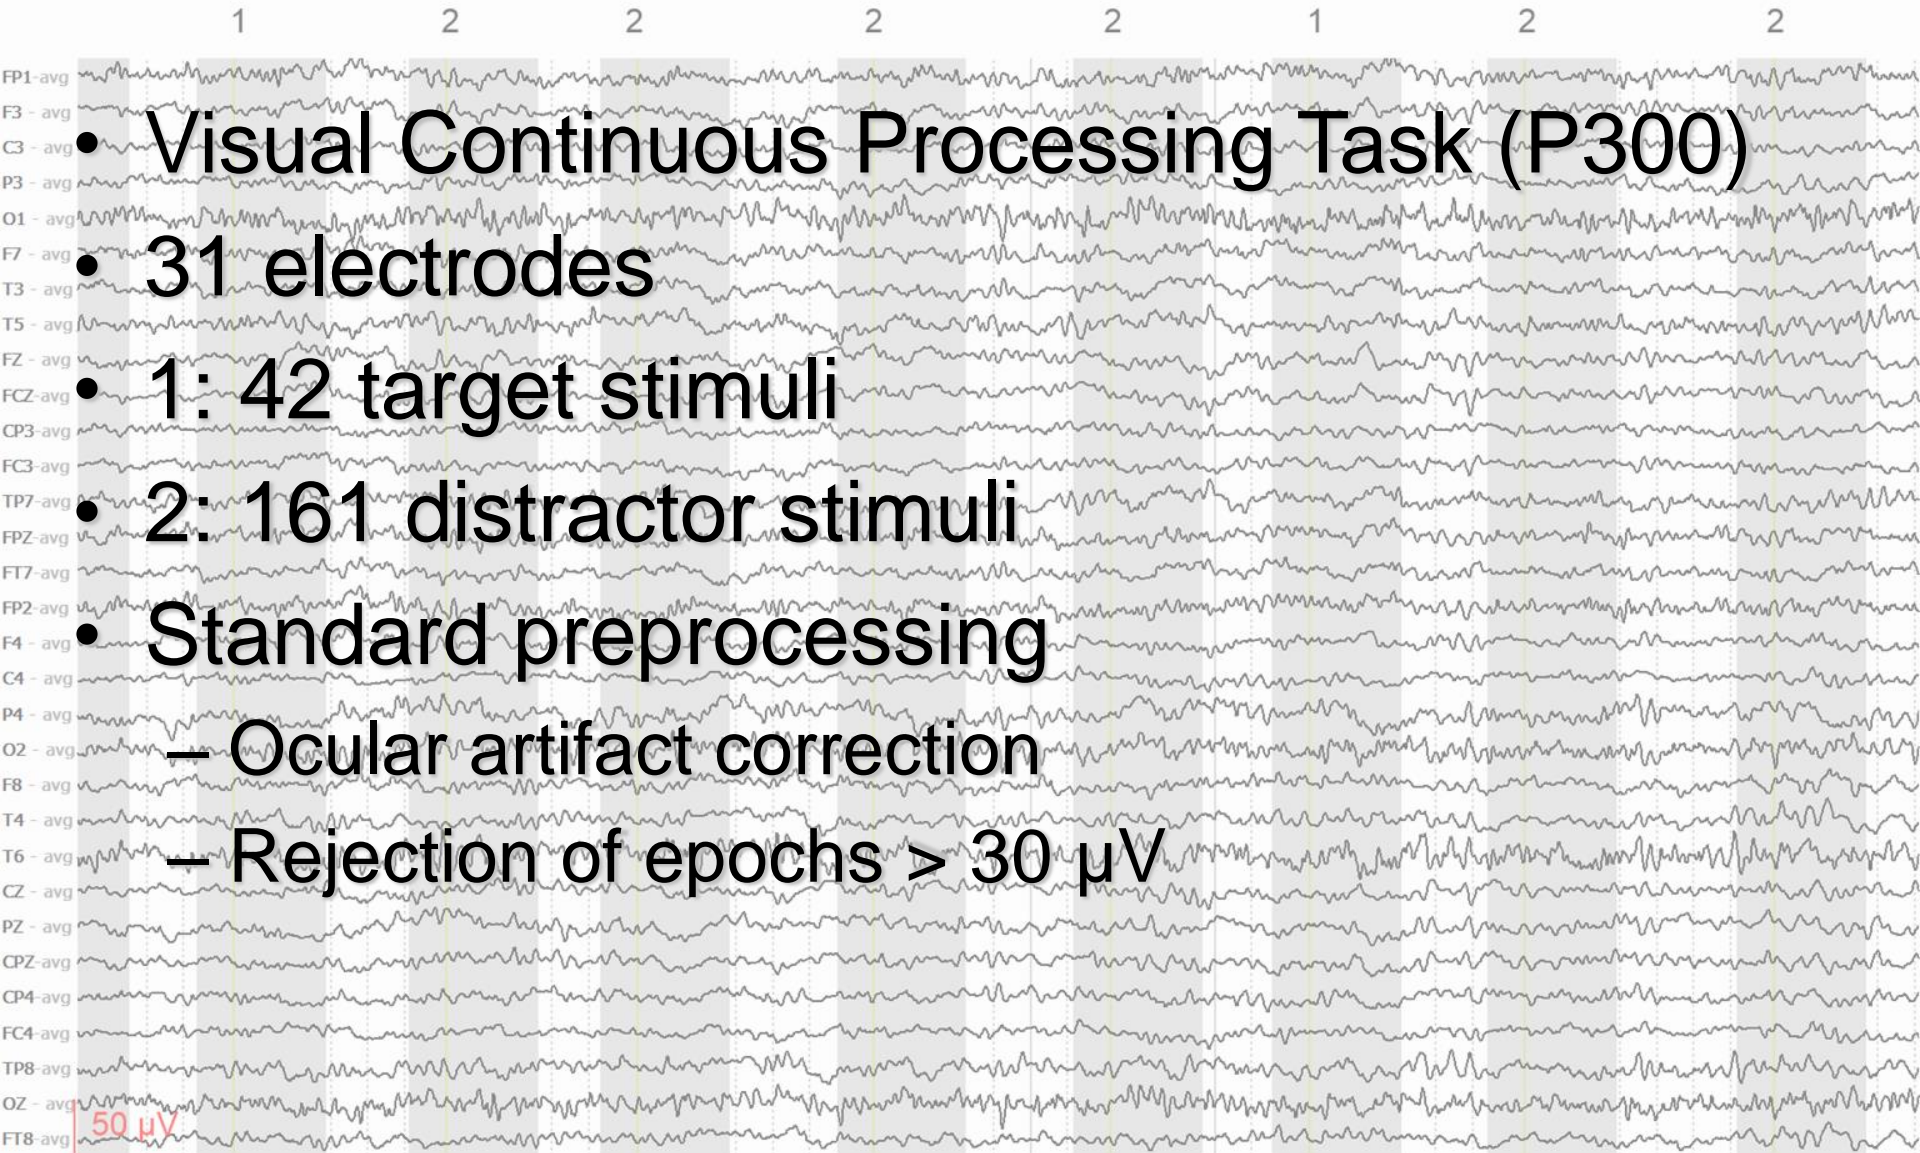

Goals

- For single-subject evoked-response EEG:
- Detect latencies of
 - consistency within epoch type
 - differences between epoch types
- Detect latencies and source locations of
 - differences between epoch types
- Sample-by-sample

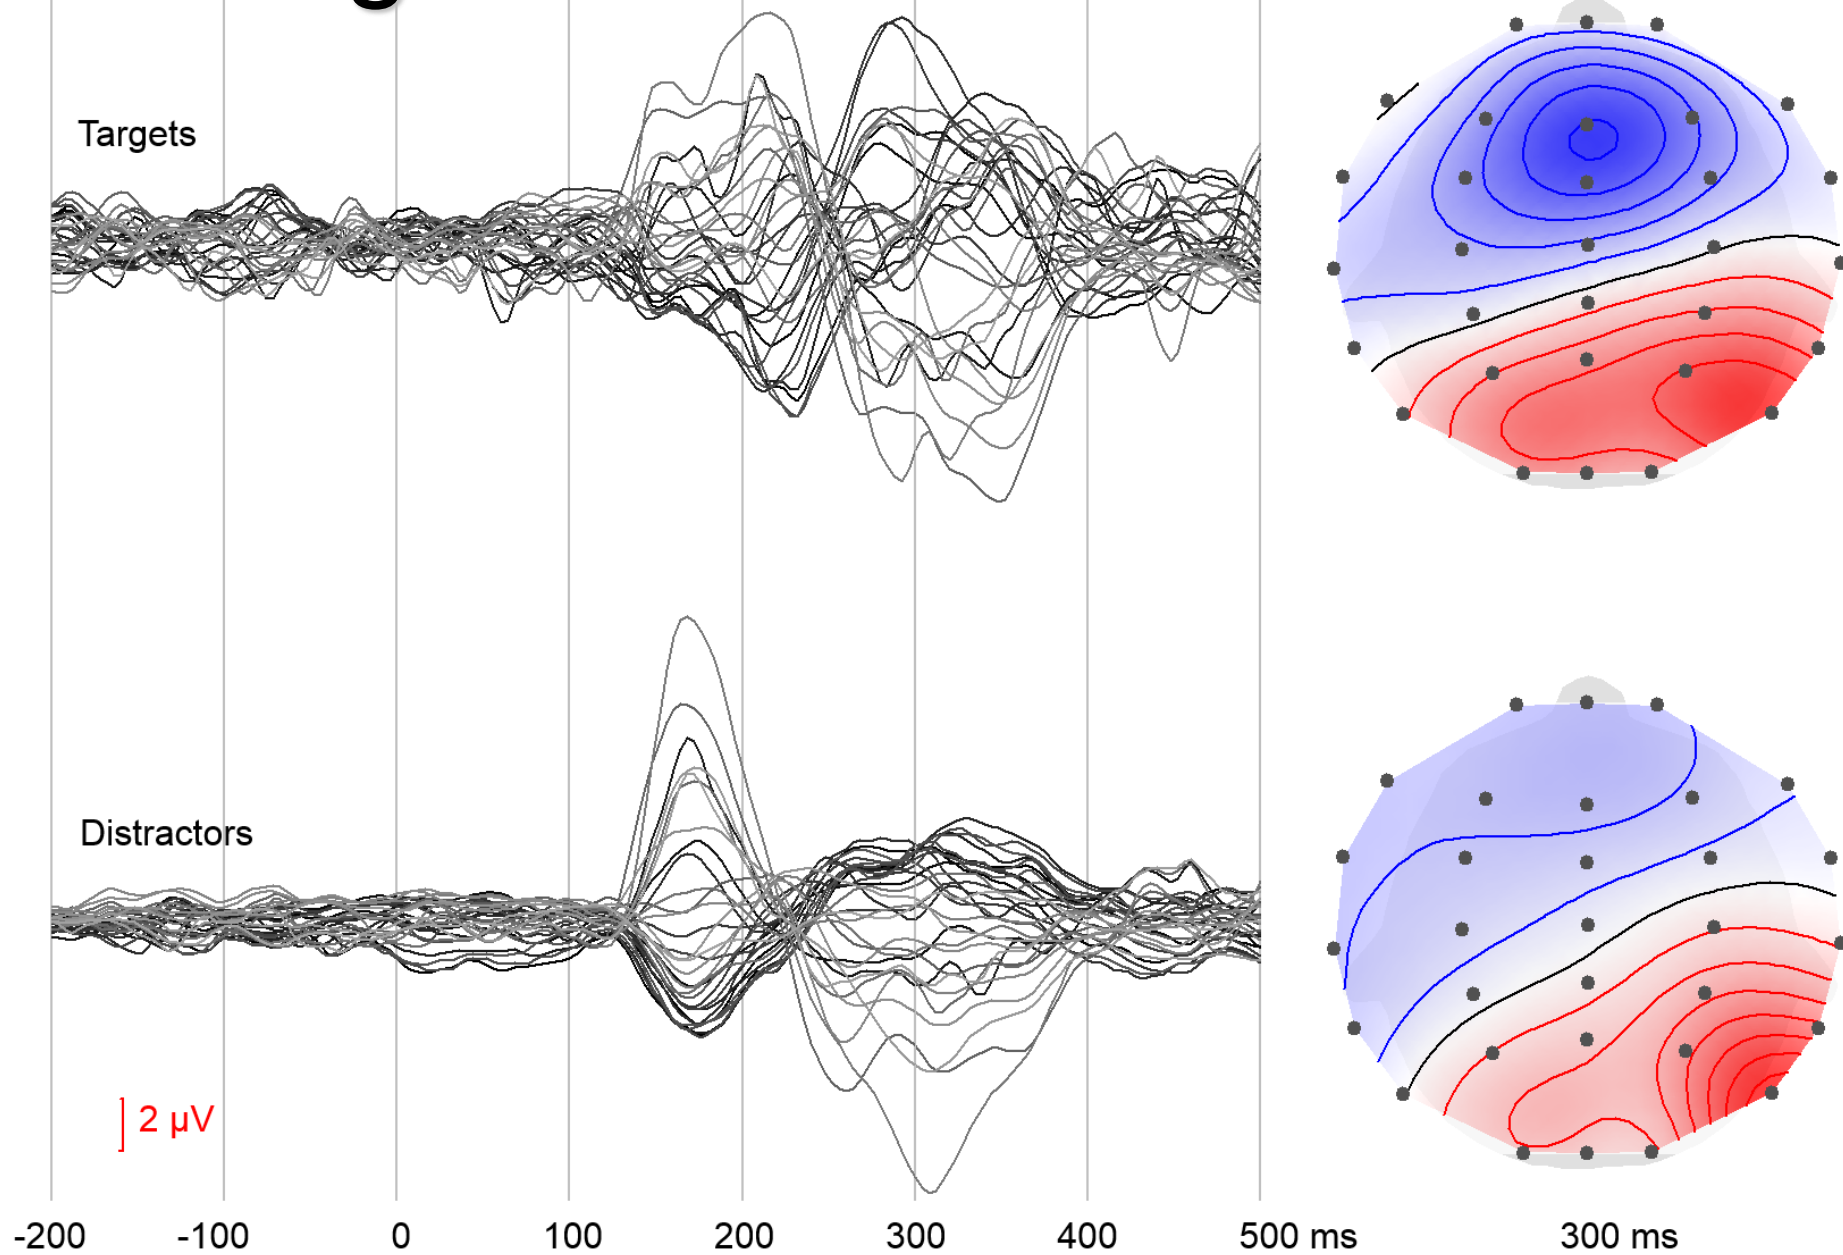

Ongoing EEG

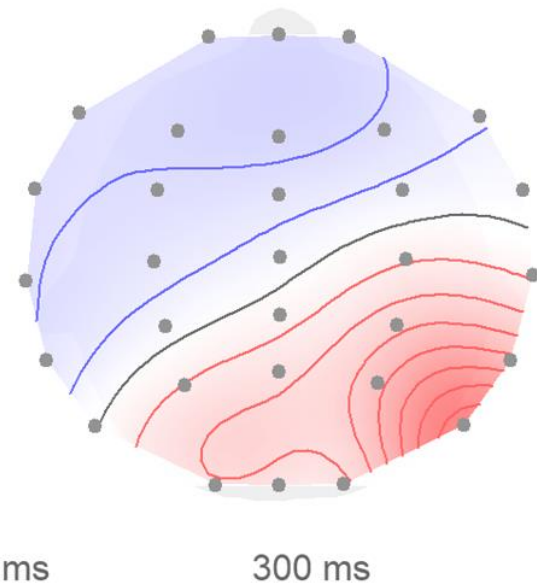

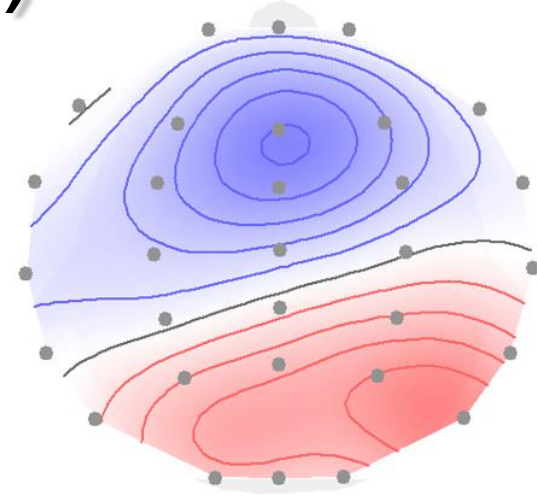

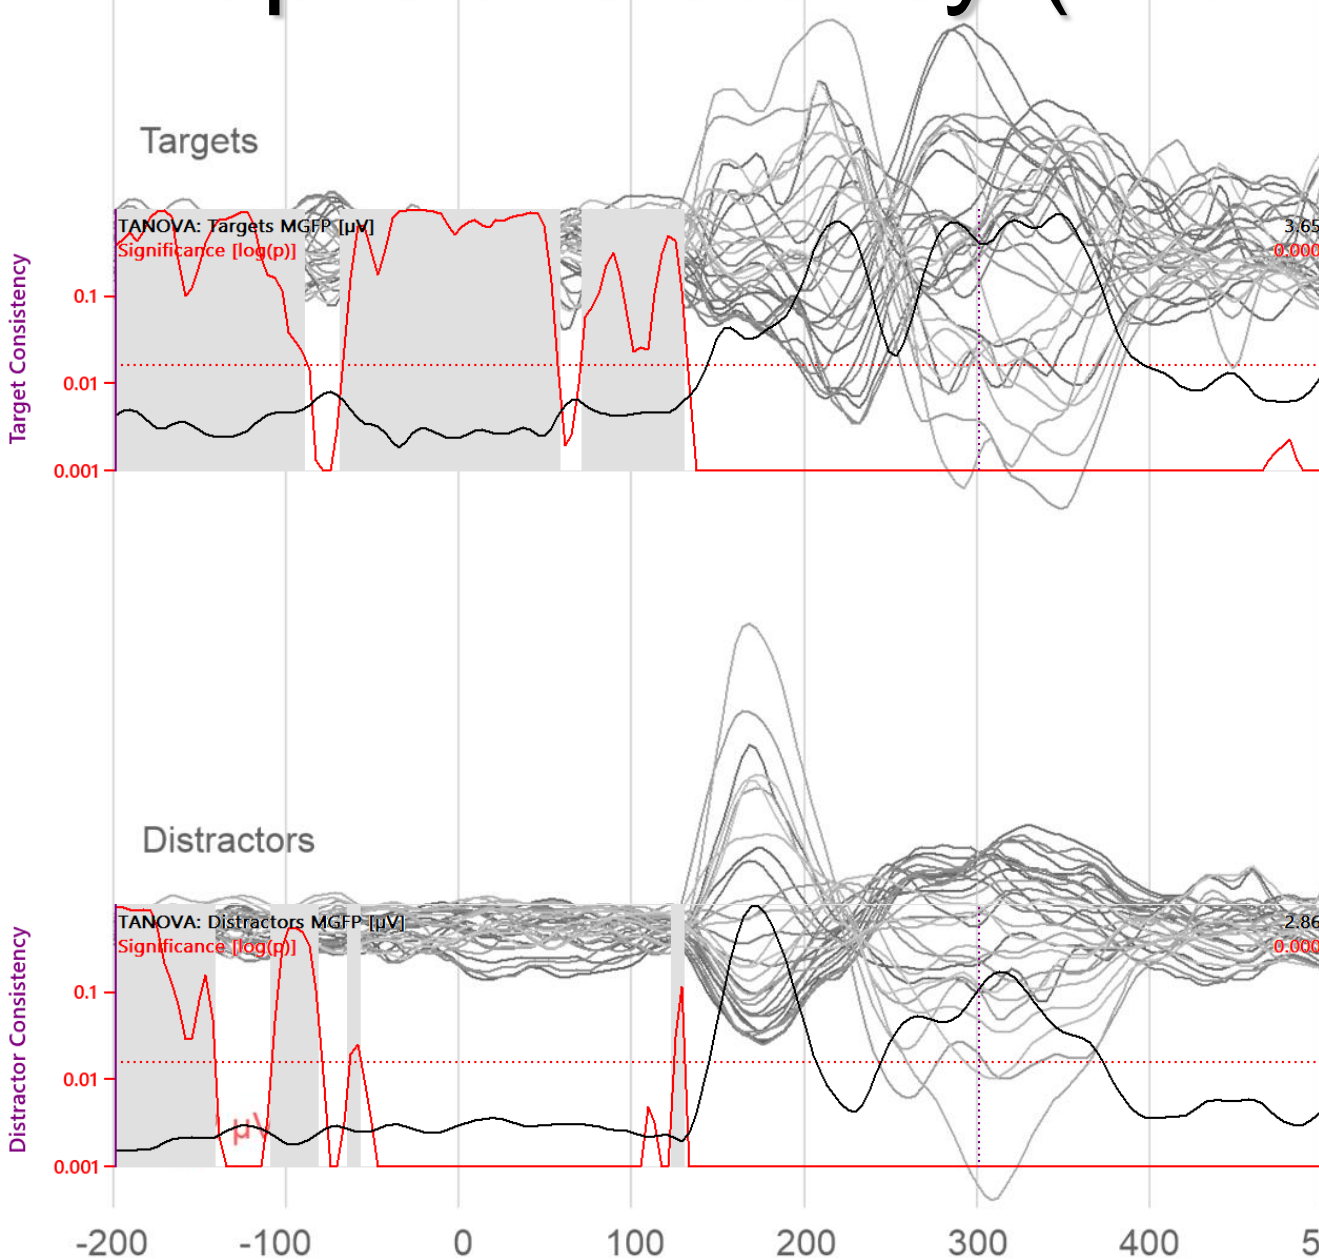

Ongoing EEG

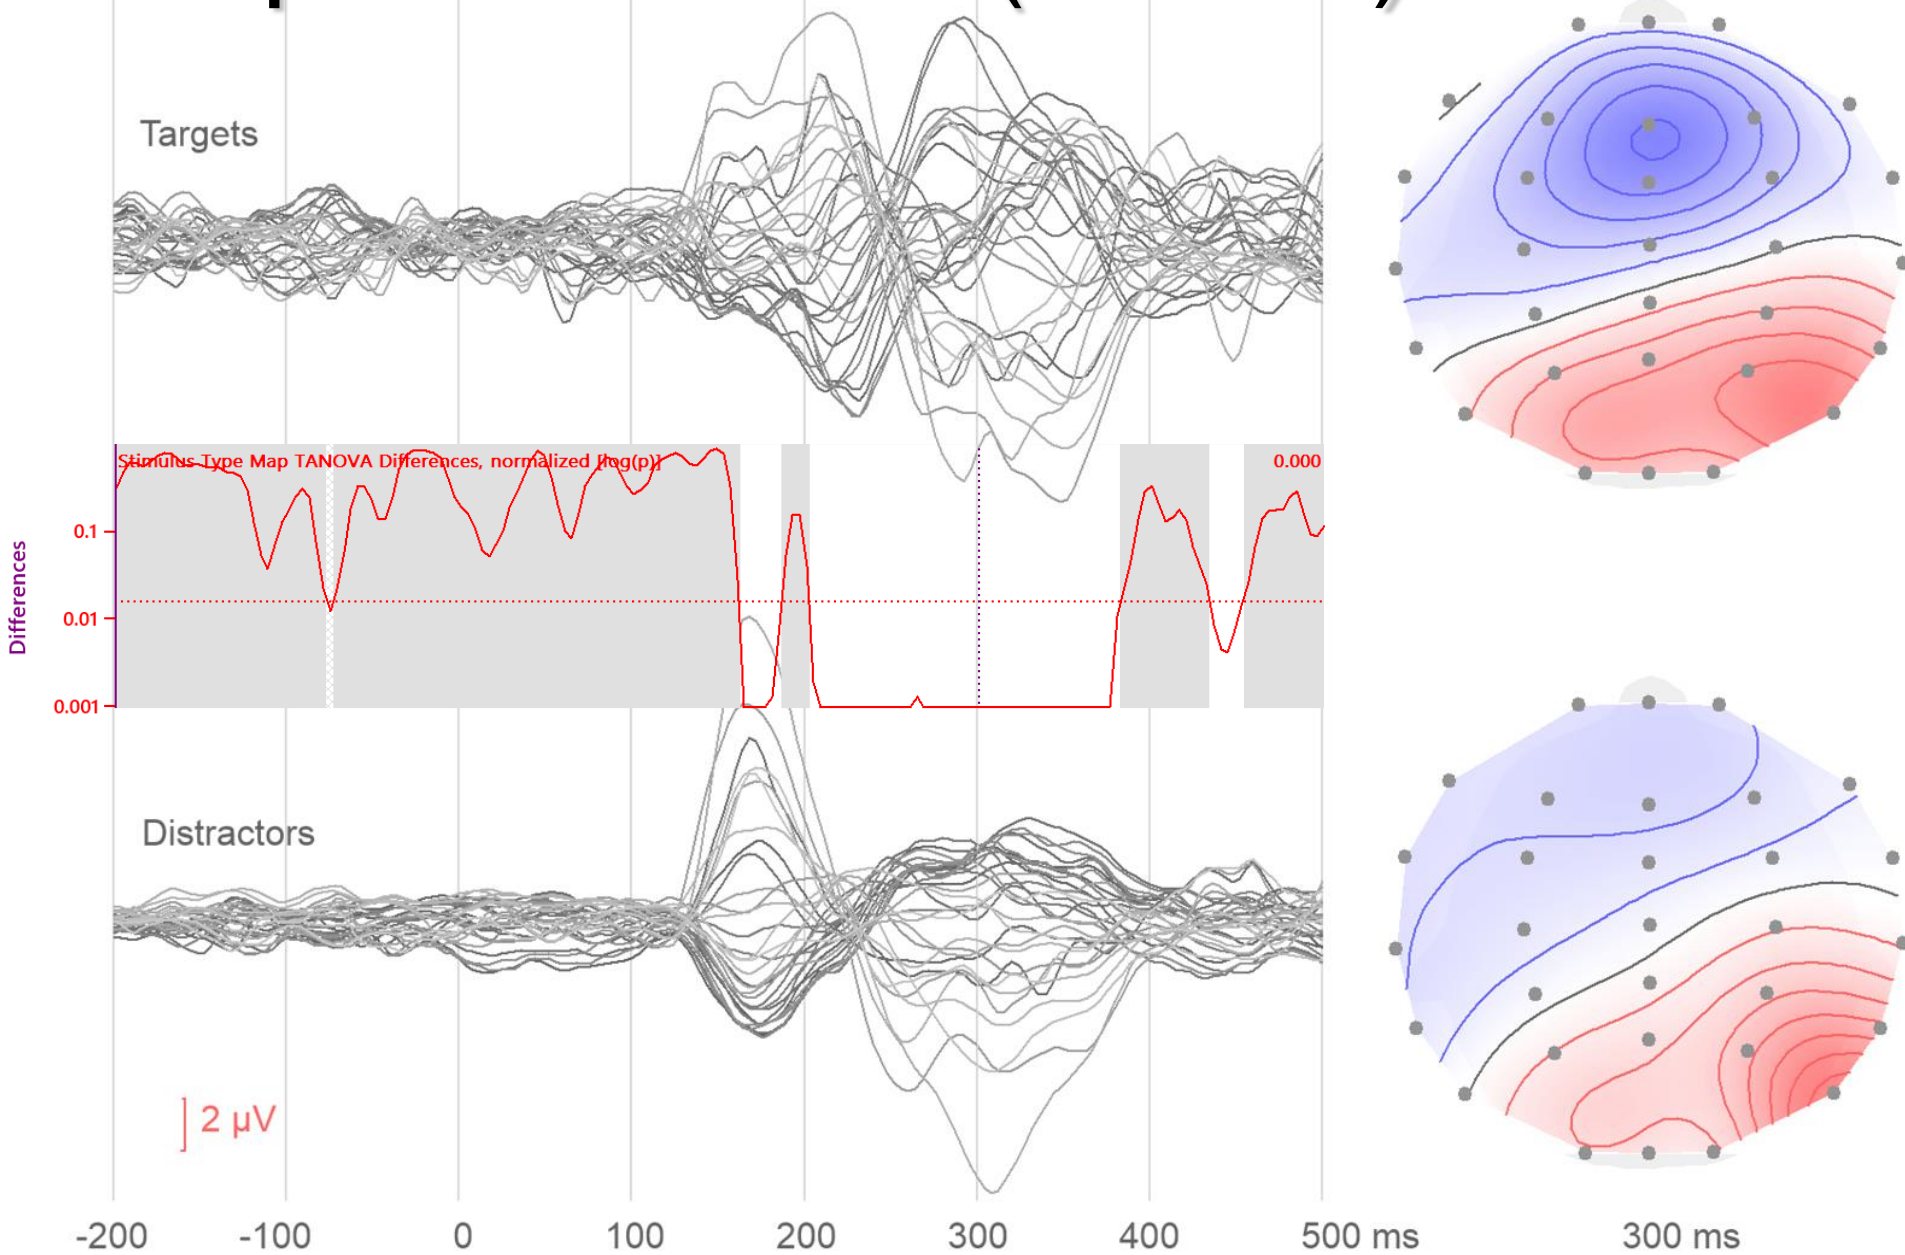

Averages

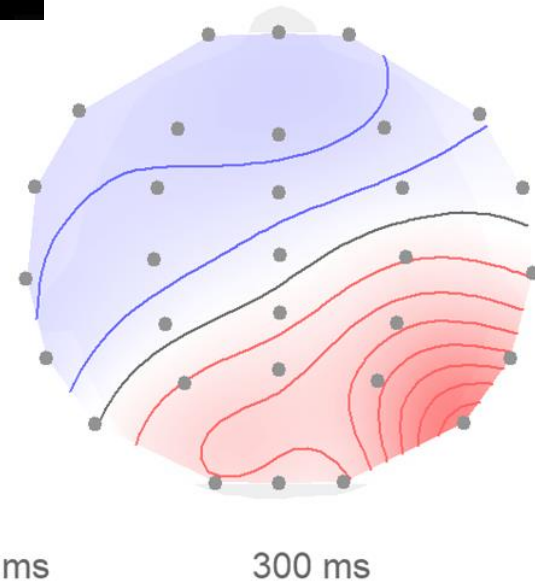

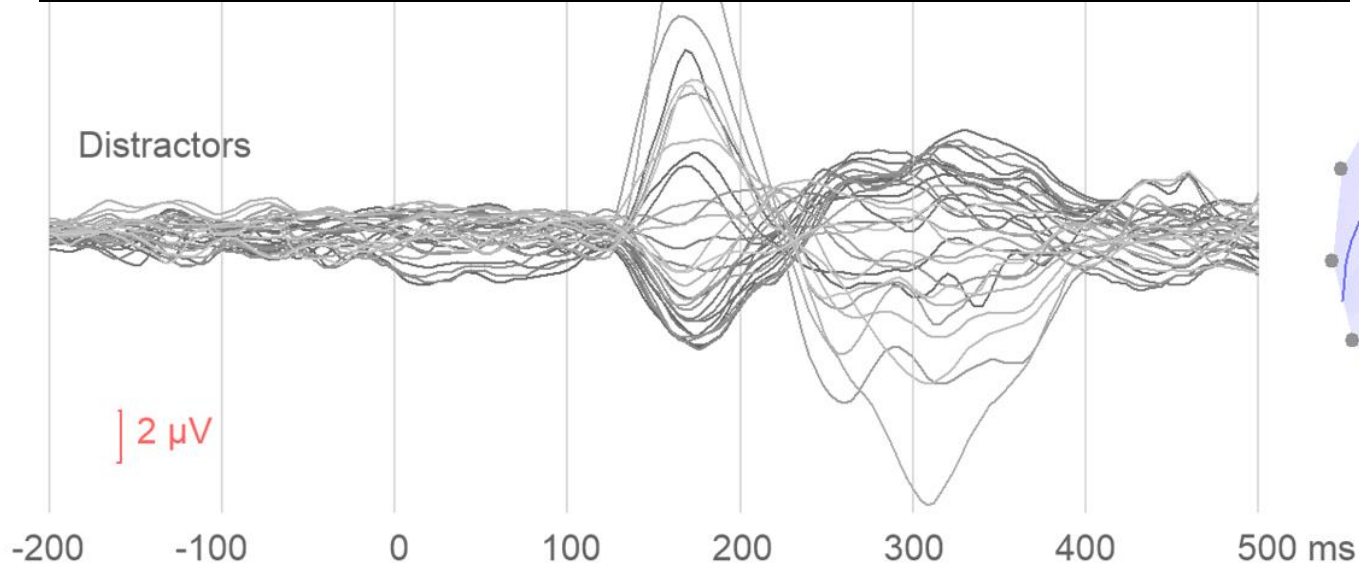

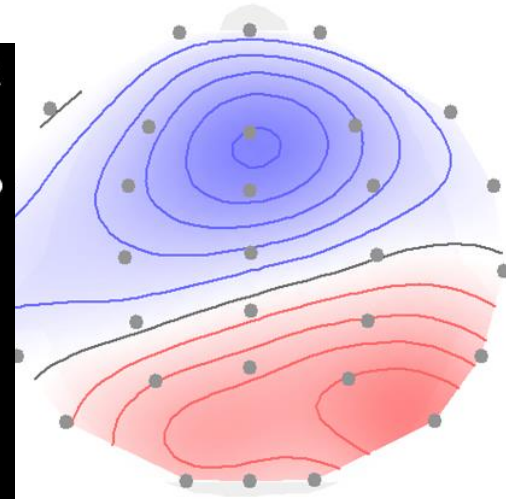

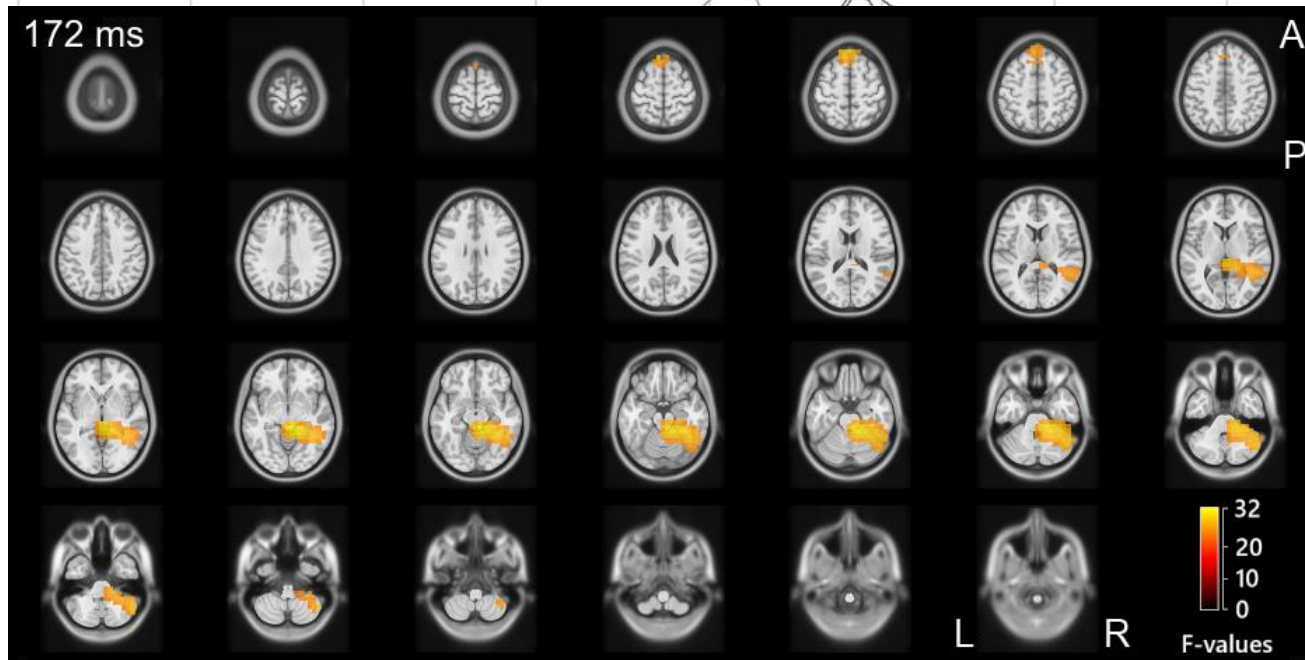

Map Consistency (within)

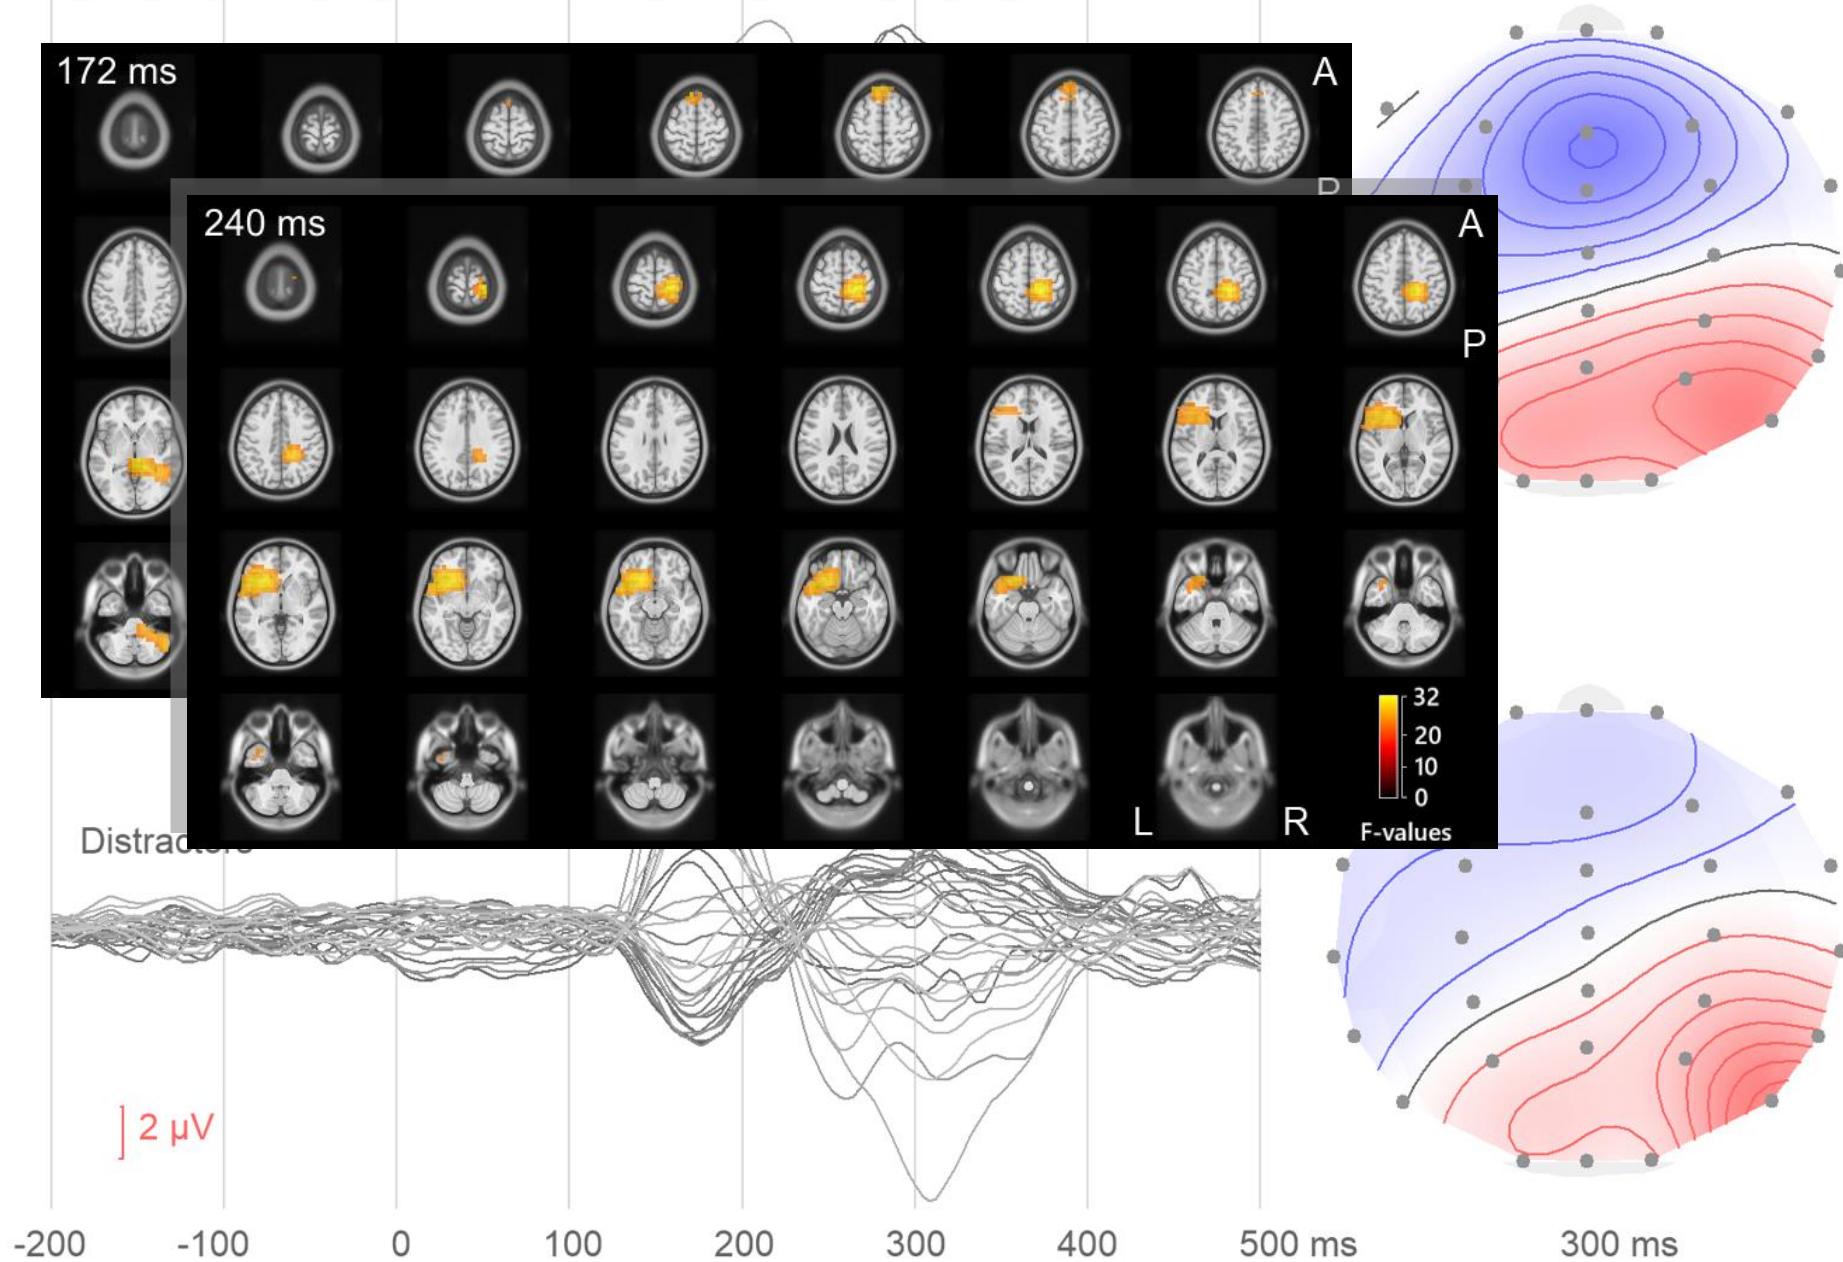

Map Differences (across)

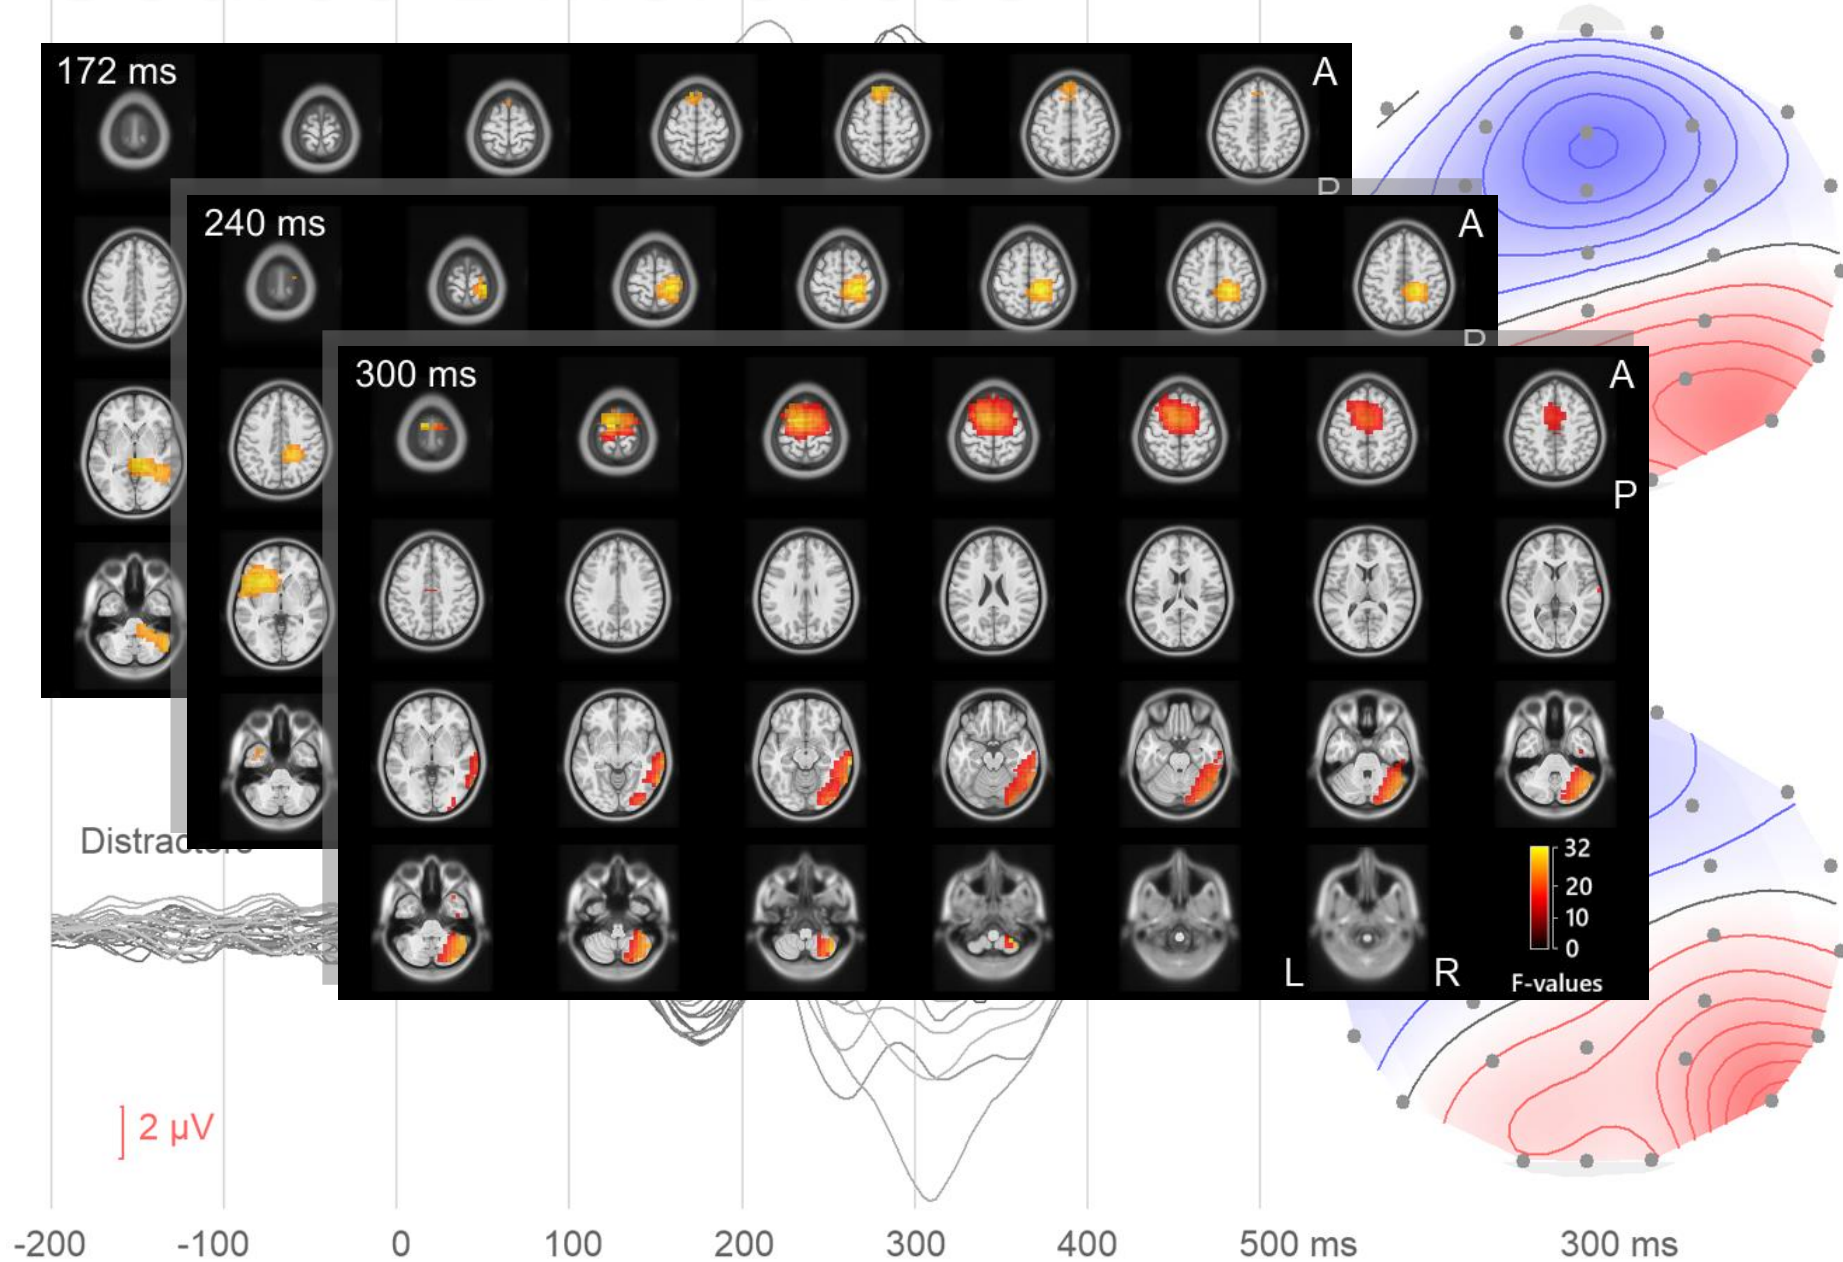

Source Differences

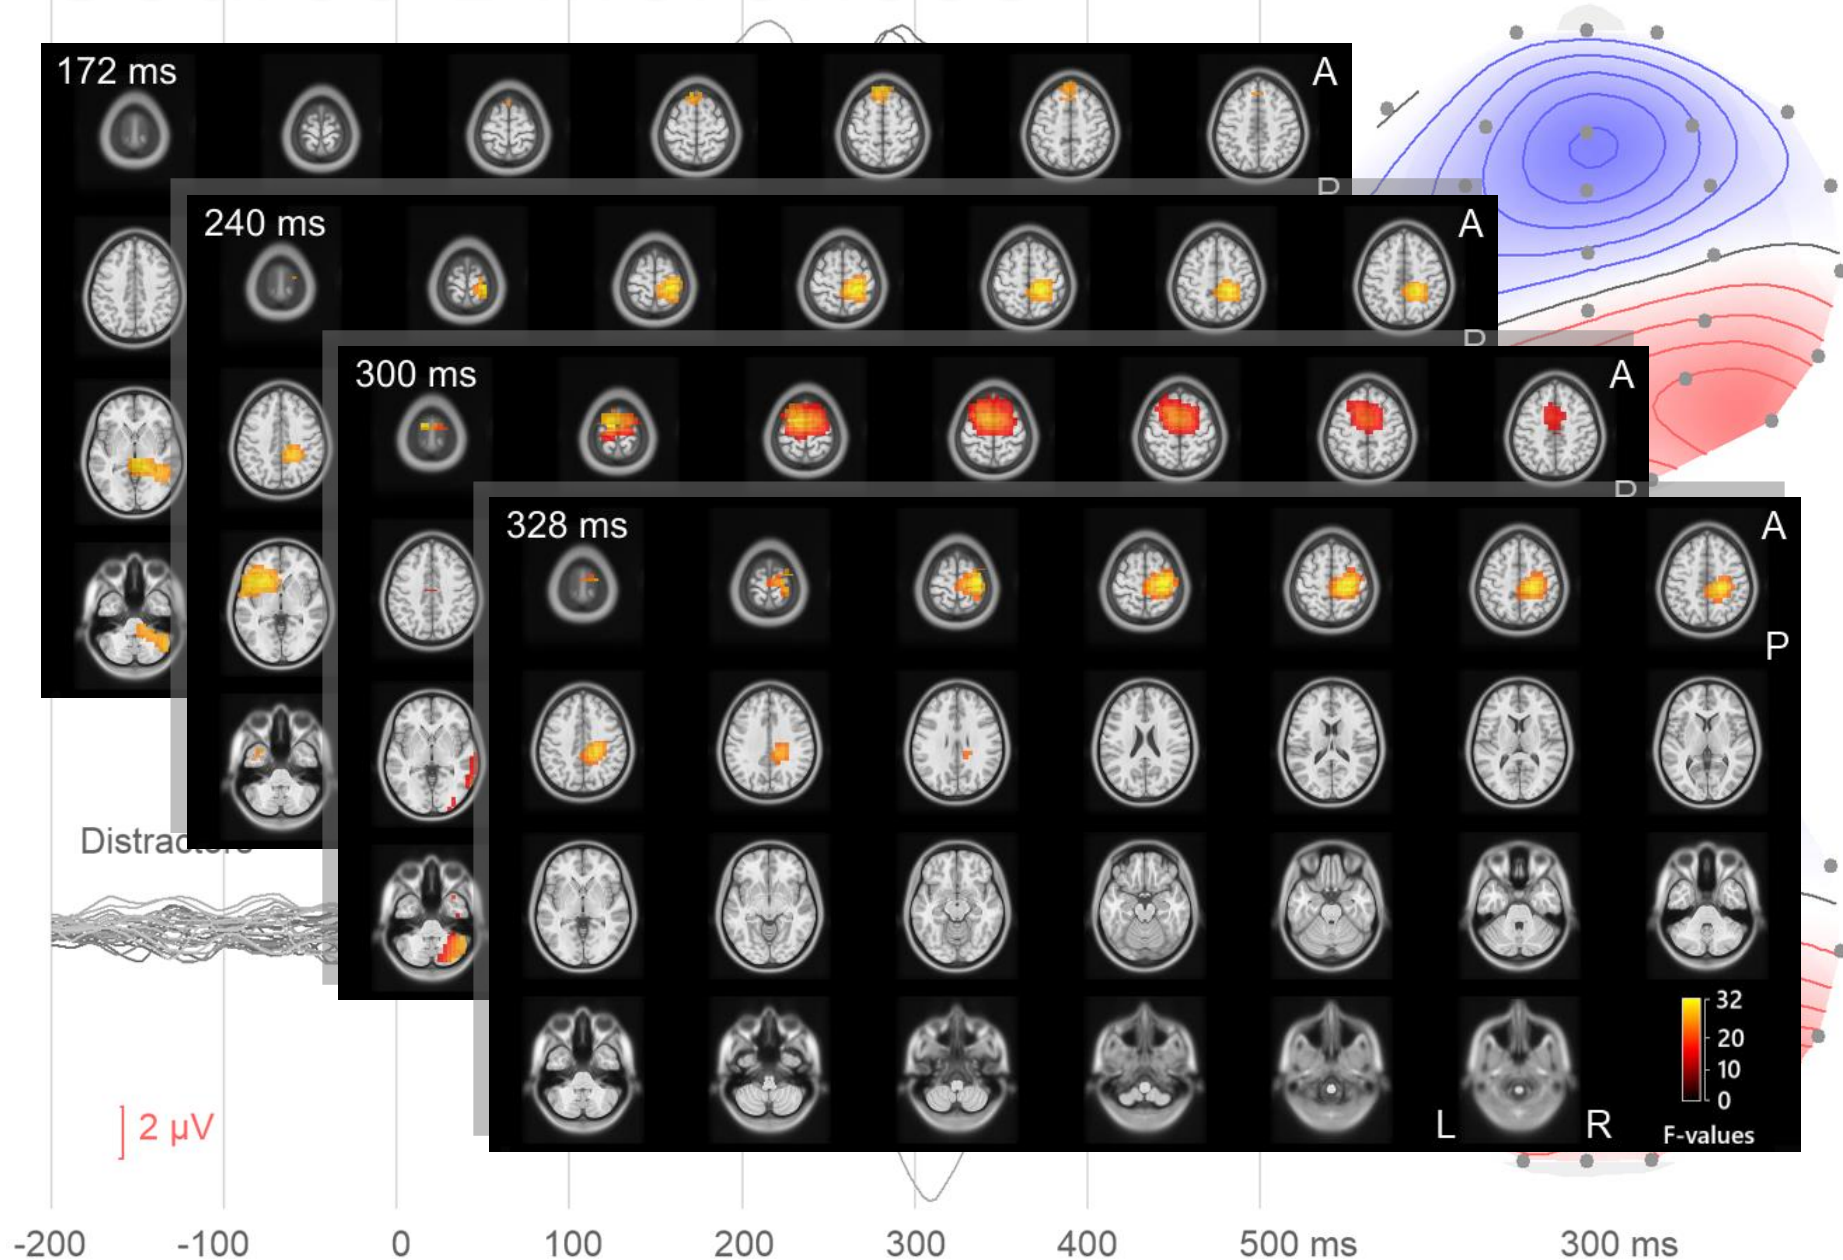

Source Differences

Source Differences

Source Differences

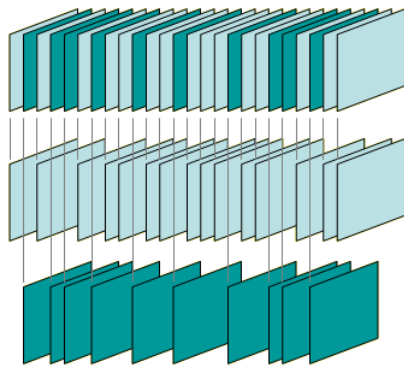

How is this Done?

- Existing work:
 - TANOVA (Koenig et al 2010): map analysis (used for EEG group studies)
 - SnPM (Nichols & Holmes 2002): image analysis (for medical imaging modalities)
- What's new:
 - Framework for epoch-by-epoch analysis
 - Single-subject data and group data
 - Apply SnPM to EEG source analysis
 - Temporal multiple comparison correction

Non-Parametric Statistics

- Compare actual and re-labeled (shuffled) data
 - re-labeling: “forget” epoch type (repeatedly)
 - significance: if actual data stands out

Shuffled Epochs

TANOVA / SnPM
metric

Non-Parametric Statistics

- Compare actual and re-labeled data
 - re-labeling: “forget” epoch type (many times)
 - significance: if actual data stands out
- Assumption-free
 - with respect to properties of underlying distribution
- Permutation-based / randomization-based
 - within- / between-subject tests straightforward
- Computationally demanding
 - typically used for group studies only
 - high-performance implementation (multi-core)

Randomization vs. Permutation

- How many tests need to be done?
 - depends on p (typical value: $p = 0.05$)
 - at least: $1 / p = 20$
 - better: $50 / p = 1000$
- Permutation: all possible re-labelings
 - 8+8 epochs: $(8+8)! / (8! 8!) = 12870$
 - 41+161 epochs: $(41+161)! / (41! 61!) > 10^{44}$
- Randomization: randomized re-labelings
 - for real-life epoch counts

Epoch-by-Epoch Analysis

- For single-subject data
 - normalize (unless effect size is relevant)
- For group data (all epochs of all subjects)
 - shuffle within or between subjects
 - normalize (optional within, mandatory between subjects)

TANOVA (topography maps)

- For two epoch types (conditions)
 - calculate average map per epoch type
 - effect size: GFP of difference map
- No multiple comparisons across sensors
- Also possible for
 - more epoch types
 - factorial designs
 - consistency test within epoch type
(by re-labeling / shuffling sensors)

CDR SnPM (source images)

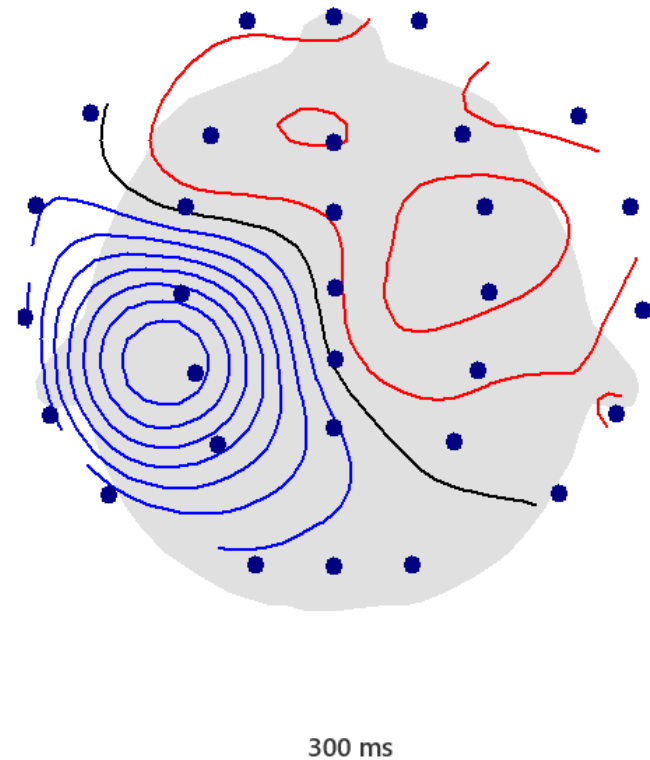

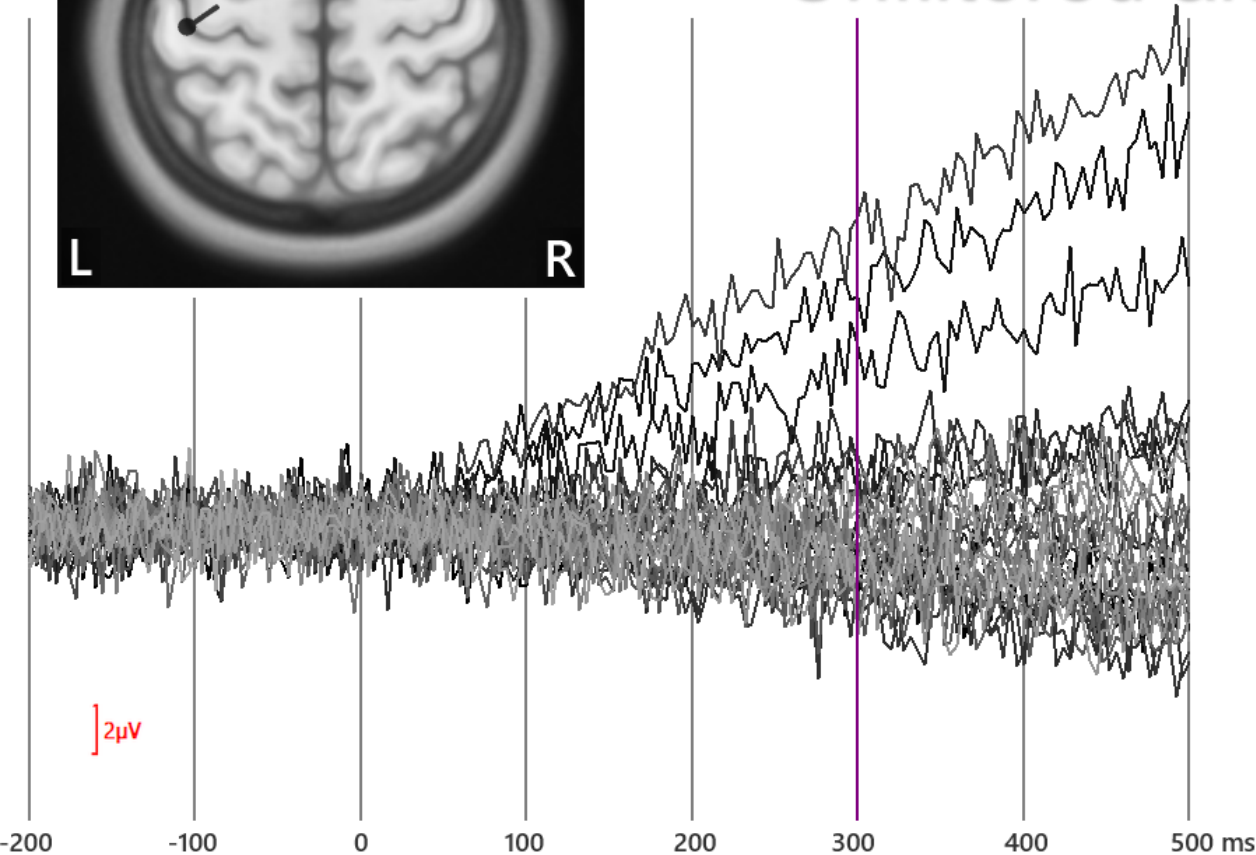

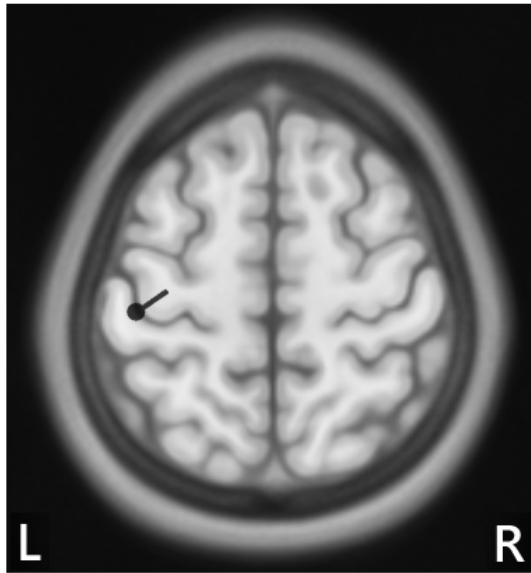

- For two epoch types (conditions)
 - calculate source activity images
for all epochs and samples (e.g. using sLORETA)
 - F-test (per location, across epochs)
 - effect size: maximum F-value across locations
- No multiple comparisons across locations
- Also possible for
 - more epoch types
 - factorial designs
 - consistency test within epoch type
(by re-labeling / shuffling locations)

Multiple Comparison Correction

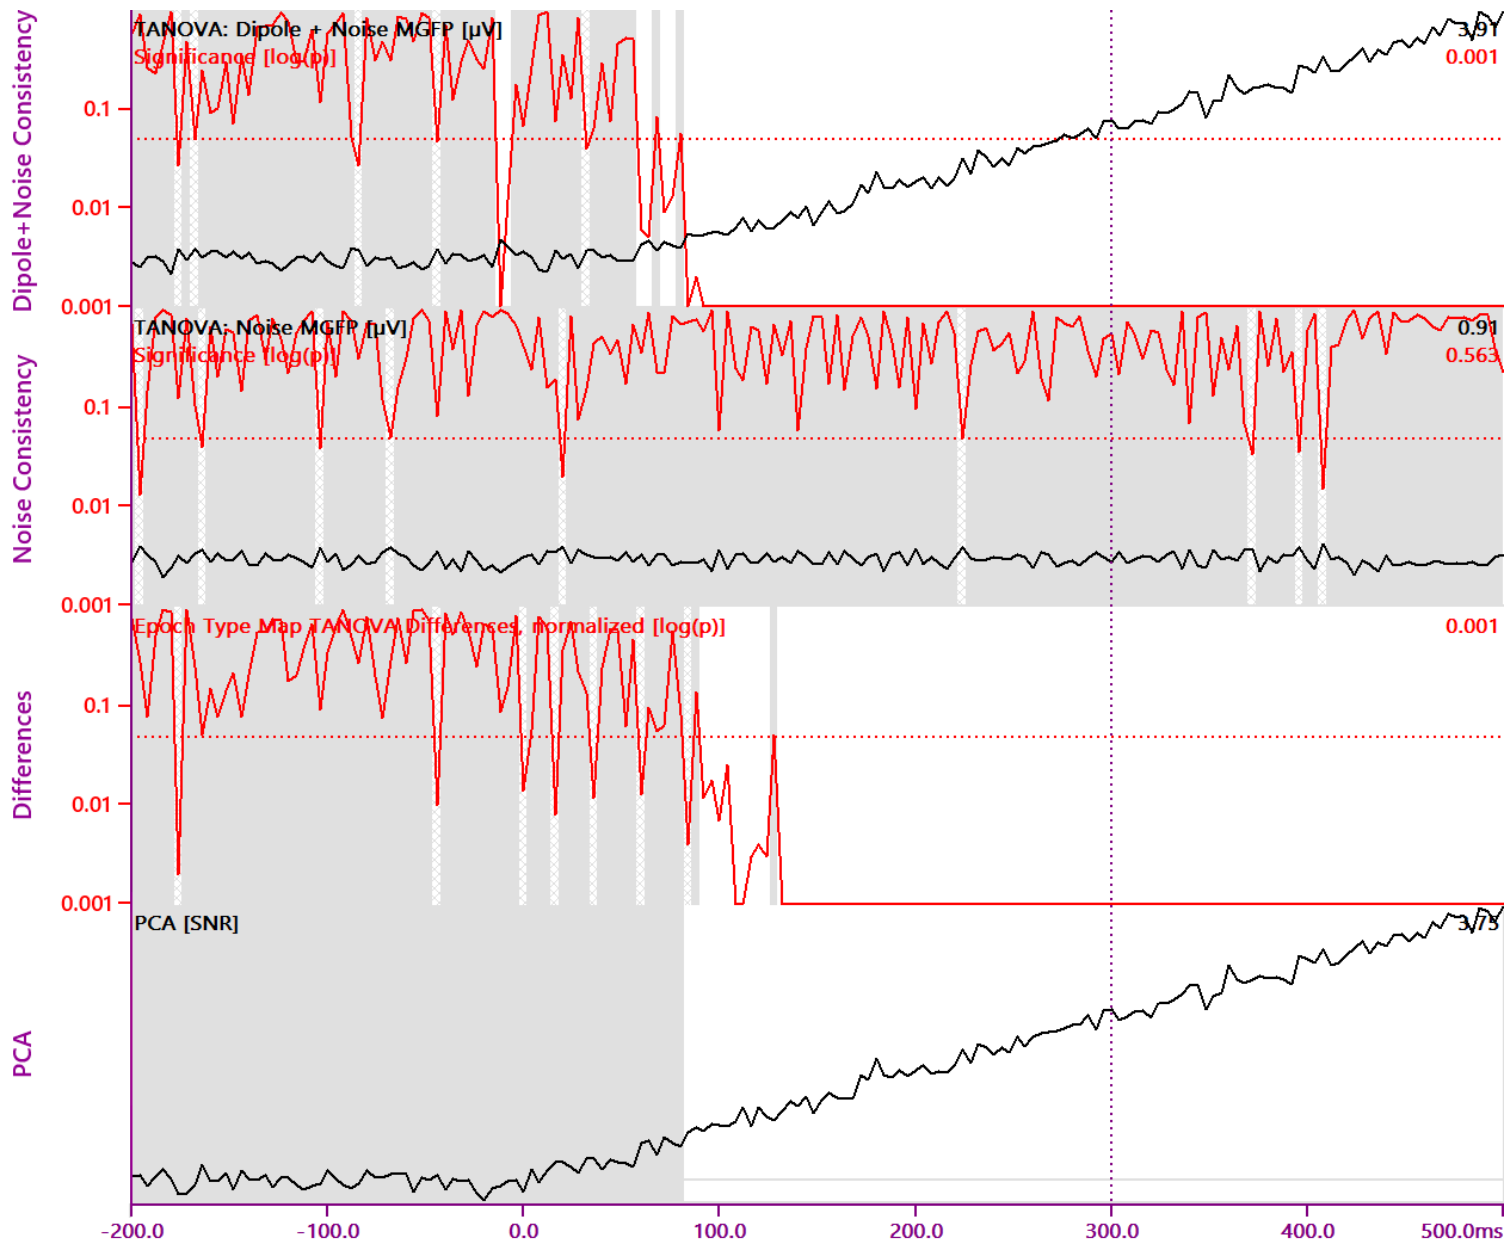

- Analysis performed sample-by-sample
 - high temporal resolution
- Typical ERP setup
 - 1000 Hz sampling rate, 40 Hz low-pass filter
 - neighboring samples are similar (how many?)
- Nyquist-Shannon sampling theorem
 - after filtering, resample at 2x filter frequency
 - $n = 1000 / (2 \times 40) = 12.5$ ways to do this
- Temporal multiple comparison correction
 - adjusted significance level based on n

A Simulation Study

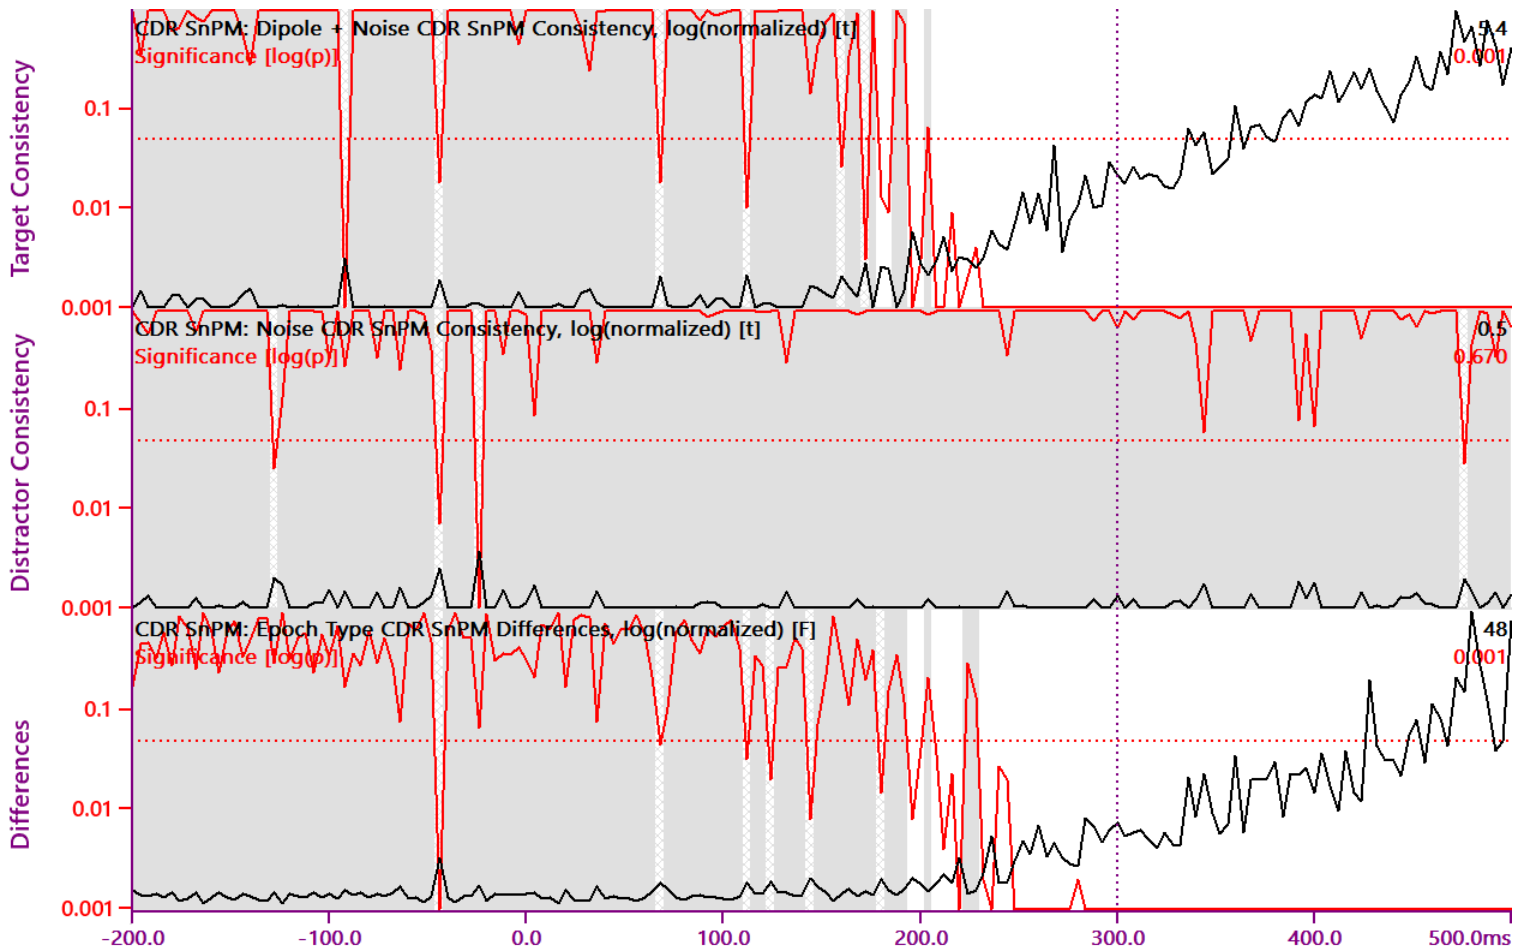

- 100 epochs dipole+noise
- 100 epochs noise only
- Unfiltered and 10Hz low-pass

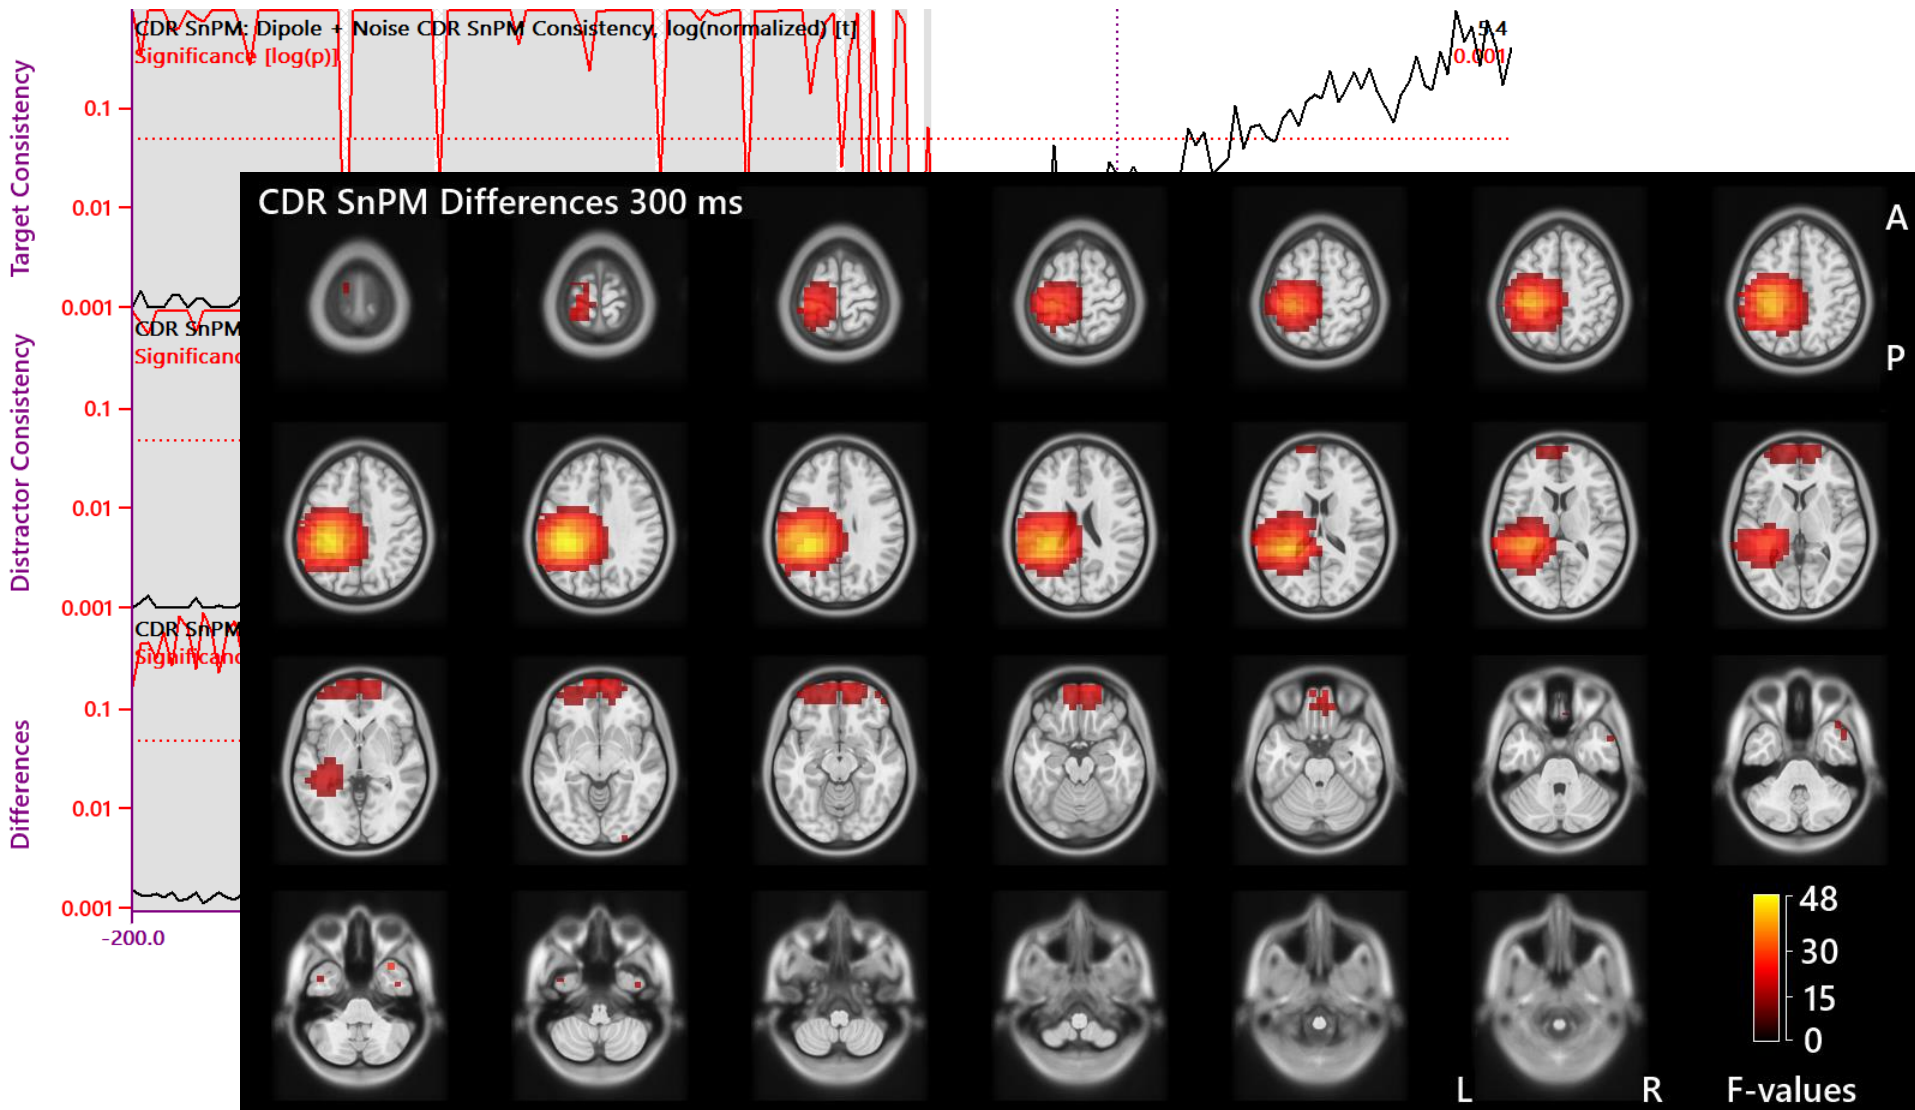

A Simulation Study: TANOVA

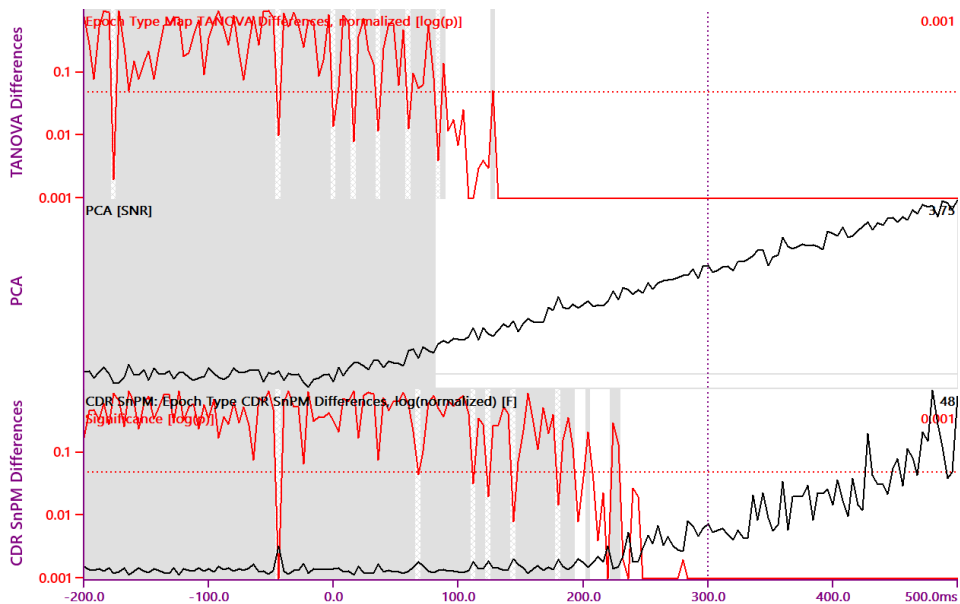

A Simulation Study: CDR SnPM

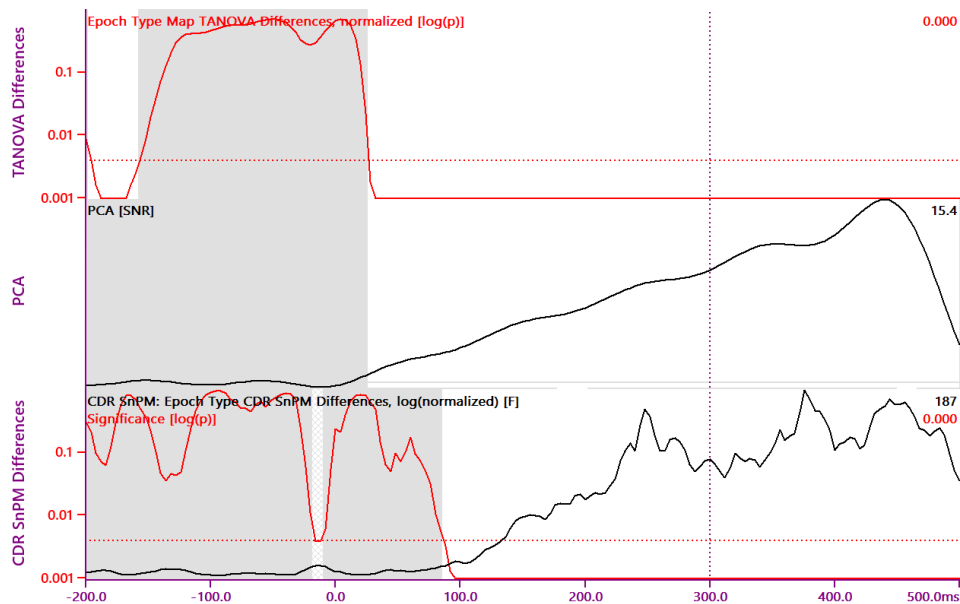

A Simulation Study: CDR SnPM

A Simulation Study

unfiltered

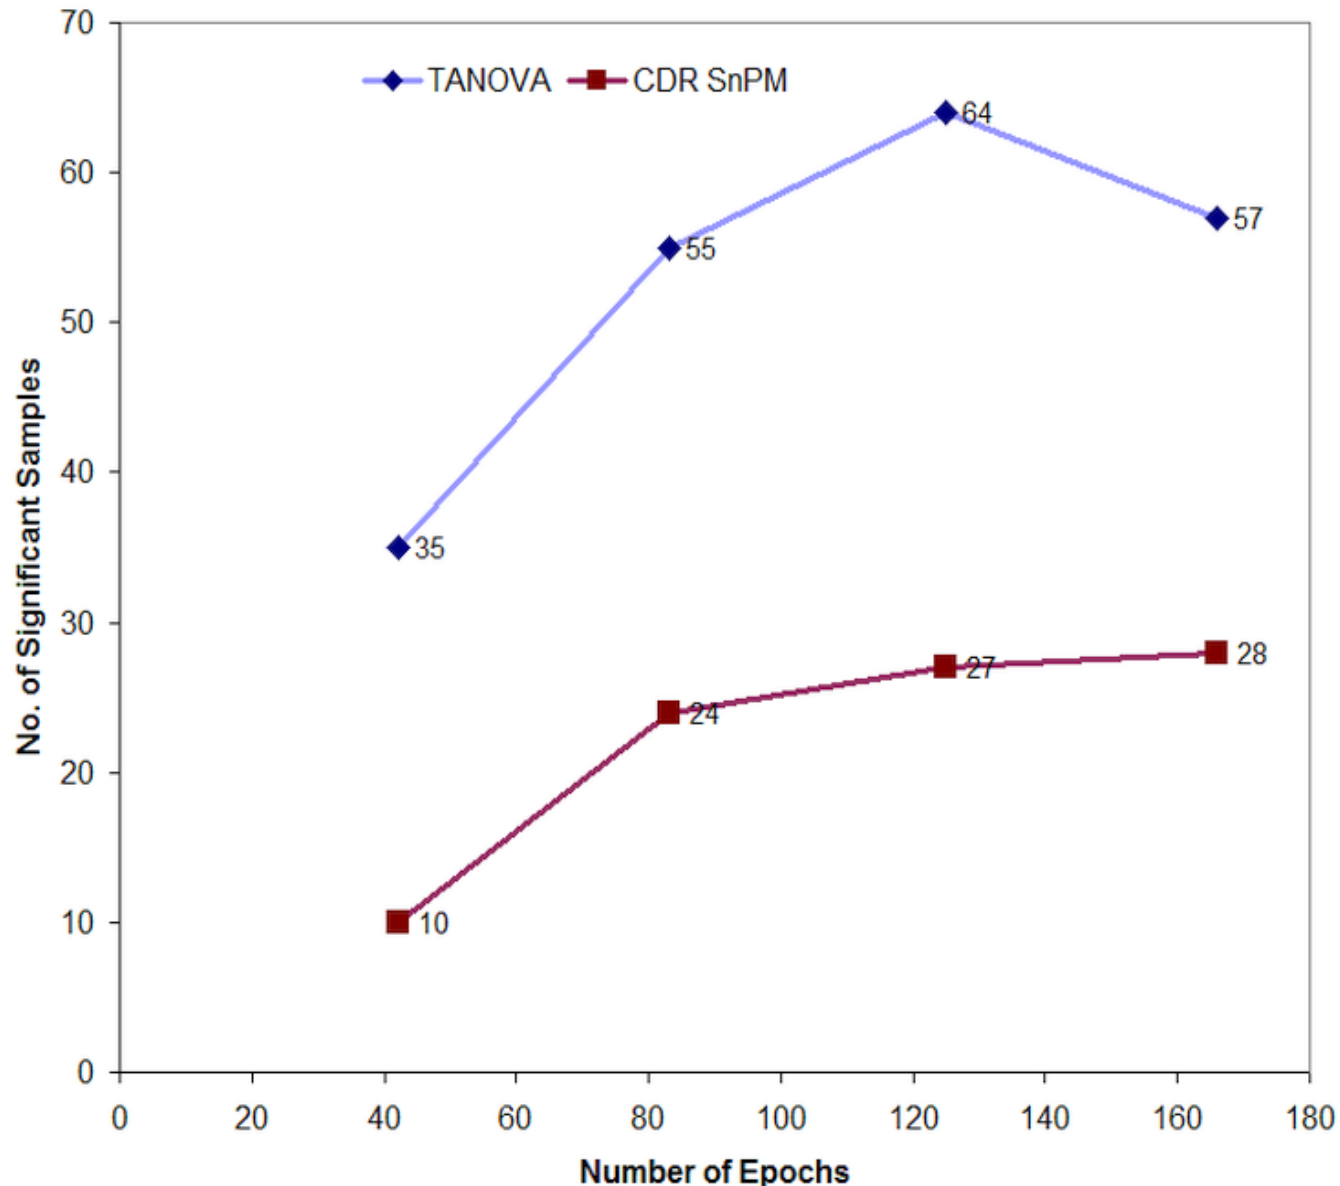

low-pass filtered

- Temporal multiple comparison correction: lower significance level for filtered data
- Less samples with CDR SnPM differences

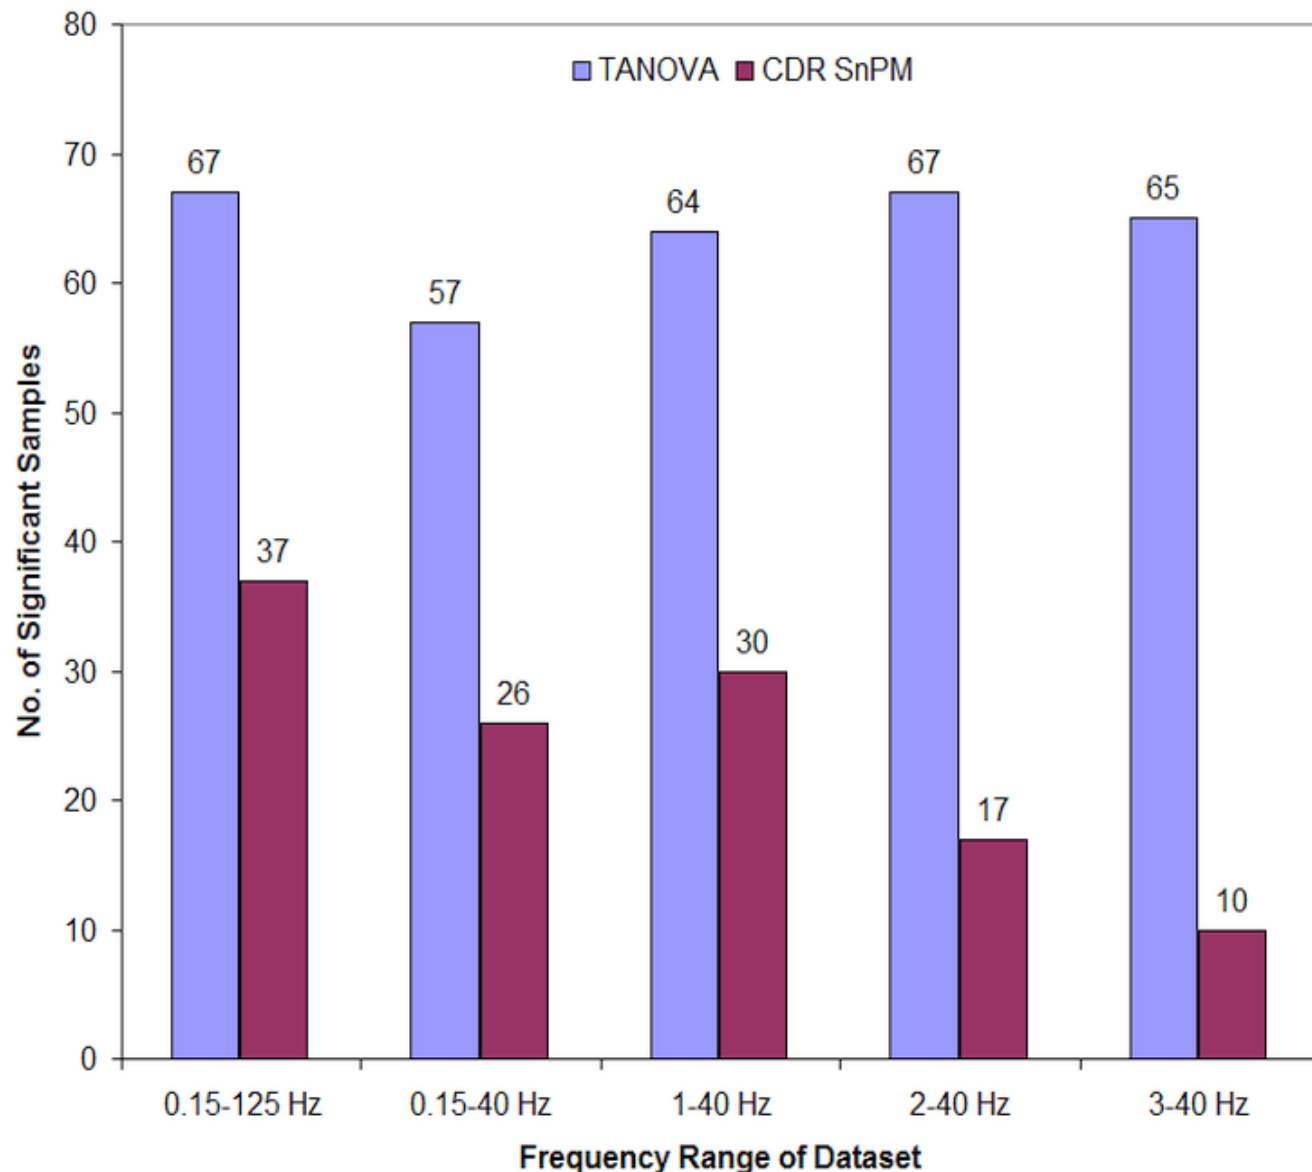

How Many Epochs?

- Different subsets of epochs
- 41+161 CPT data
- No. of samples with significant differences

Different Filter Bands?

- Different high-pass, low-pass
- 41+161 CPT data
- No. of samples with significant differences

Conclusion

- For single-subject (and group) ERPs:
- Detect latencies of
 - consistency within epoch type
 - differences between epoch types
- Detect latencies and source locations of
 - differences between epoch types
- Sample-by-sample
 - with temporal multiple comparison correction

In an Event-Related Potential (ERP) or Event-Related Field (ERF) experiment, an Electroencephalography (EEG) or Magnetoencephalography (MEG) device records the brain response related to a sensory, cognitive, or motor event. Depending on the experimental design, events (stimuli or responses) may be of the same or of different types. Data segments with distortions such as ocular, cardiac, or muscle artifacts are later detected and artifacts are either reduced or excluded from further processing. After splitting the data into epochs time-locked to events, many repetitions per event type are available and usually averaged and compared. After averaging, though, it is no longer possible to establish whether and for which latencies the averaged waveforms differ significantly between event types, nor whether the trials (epochs) of a given type yield significant averages in the

1. Introduction

In Event-Related Field (ERF) experiments, stimuli - often of several different types - are presented repeatedly, and the subject's brain response is recorded using MEG. After removing artifacts and epoching the data, many repetitions per stimulus type are available, which are later usually averaged and compared. At this stage, though, it is no longer possible to establish whether and for which latencies the averaged waveforms are significantly different between stimulus types, nor whether the trials (epochs) for a given stimulus type are consistent enough to warrant averaging them in the first place. A statistical analysis of all individual epochs can provide exactly this information.

Traditional statistical measures in channel space such as the t-test make disputable assumptions regarding repeatability and independence (Murray et al. 2008, Koenig and Melie-Garcia 2009). Therefore, a new non-parametric family of methods has recently attracted attention as it became computationally feasible for the analysis of Event-Related Potential (ERP) group studies (Murray et al. 2004). Although - misleadingly - referred to as Topographic Analysis of Variance (TANOVA), no analysis of variance is being conducted, but rather a non-parametric randomization test.

In this contribution, a framework is proposed that allows the application of TANOVA not only to individual averages in the context of an ERP group study but to the un-averaged individual epochs themselves, as obtained in a Mismatch Negativity (MMN) MEG experiment.
